Article History: Received 22nd February 2022; Accepted 14th April 2022; Published 10th May 2022

ABSTRACT

The objective of the study was *in vitro* micro-propagation through axillary buds and shoots peaks culture of each root stock with randomized design in the three replications. For callus inductions lateral apples have been cultured on MS medium contained 30 g/L sucrose, 7 g-L agar, vitamins and supplemented with 1, 2, 3 and 4 mg-L of NAA mixed with 2.0 mg-L of Kn were examined. In shoot multiplication, MS media fortified with 0.5, 1.0, 1.5 and 0.2 of mg-L of BAP and 0.5, 1.0, 1.5 and 0.2 of mg-L of Kn and mixtures of 0.5 mg-L BAP with 0.5 mg-L of Kn and 2 mg-L BAP with 0.5 mg-L of Kn have been examined. The data shows that treatments with 0.5mg-L has shoots growths were decreased compared to other treatments. In root induction, two groups of media MS 0.25, 0.5, 0.75 1.0 mg-L of AIB, and 0.25, 0.5, 0.75, 1.0 mg-L of NAA were used for evaluations and higher roots length were recorded at 0.25 mg-L of IBA. In conclusion, it is recommended to use *in vitro* propagation protocols for fruit multiplication in nursery to farmers to produce a large amount of seedling within a short period of time.

Keywords: Apple, Auxin, MS medium, Cytokinin, and Growth Regulators.

INTRODUCTION

The apple tree is presumably the foremost tree has been cultivated, and its fruits are bettered through selection over thousands of times (Potter *et al.*, 2007). Apples are the natural source of dietary mineral salts, vitamins, antioxidants, fiber, organic acids and sugars that is why there have been developed many technologies of breeding and preservation. Conventional clonal propagation methods such as budding and grafting to maintain disease free root stocks require elaborate nursery facilities which are time consuming as it will take many years to reach sizable numbers for commercial purposes; slow, labor intensive and may require large amounts of land. Alternatively, success *in vitro* clonal propagation strategies have been suggested in apple for marketable applications in the tree fruit productions. The *in vitro* micropropagation of apple fruits has a remarkable function in the production of healthy, and in quick propagation with suitable traits (Budabus *et al.*, 2010). Several strategies are being developed for the production of diseased fruits using tissue culture techniques. These techniques maintain promise for

generating greater plant material in a shorter period of time with much less labor and at decrease costs. These *in vitro* propagation strategies yield a mean of four to six shoots from a single source shoot over a length of four weeks (the switch generation (Keresa *et al.*, 2012).

Owning its diverse climatic Zones, Ethiopia is a suitable country for agriculture including apple cultivation. However, there has been a decline in the quantity and quality of apple cultivation due to problems such as pests, diseases, high labor costs and marketing issues. Mass propagation through conventional clonal propagation methods such as budding and grafting requires elaborated nursery facilities. It is a time consuming to reach significant numbers for commercial purposes; slow, labor intensive, and can require massive quantities of land. A variety of plant regeneration protocols may be utilized for apple crop improvement through the application of biotechnological techniques, and one of such techniques is micro-propagation via tissue culture.

Micro-propagation of apple has played a necessary function in the mass production of disease-free flora with

perfect features (Bommineni *et al.*, 2001). Tissue culture is, therefore, one of the biotechnological strategies that play a critical function in the distribution of germplasm, conservation, secure alternate of internal planting material and rapid propagation of newly selected hybrid cultivars. With this impressions, several researchers (Dobránszky and Teixeira da Silva, 2010; Boudabous *et al.*, 2010) have described the regeneration of *apple* via micro-propagation has a remarkable advantage over the conventional method. However, different researchers use explants from different parts of apple plants, apply different sterilization techniques and use different growth hormones in different concentrations for micro-propagation. Nonetheless, the optimality and reproducibility of the protocols to achieve the greatest result for a wide range of genotypes are always under question. Accordingly, in view of this significance the study has been designed to explore micro-propagation of apple via *in vitro* micro-propagation of apple (*Malus Domestica*) via axillary shoots and shoot apices culture techniques.

MATERILES AND METHODS

Description of the Experimental Site

The experiment became performed at Haramaya university of Plant Biotechnology in eastern part of Ethiopia. The area is far away 520Km East of Addis Ababa. Haramaya University is located 5km from Haramaya town between Harar and Dire Dawa 17 and 40 km respectively. It is also situated in the semi-arid tropical belt of eastern Ethiopia. The area also has a relative humidity about 60 to 80%. The Minimum and maximum annual temperatures range from 6°C to 12°C and 17°C to 25°C, respectively.

Plant Material Collection

Explants were obtained from local area varieties as a source of lateral bud explants. They were originally obtained from lateral bud by using sterile scissor. Stock plants were maintained and inoculated with MS (Murashige and Skoog, 1962) media complemented with different concentrations of cytokinin (BAP and Kn). Then the vessels had been transferred into growth room and arranged of the shelves at 25±2°C under white fluorescent light of 20 µmolm⁻²s⁻¹ intensity for 16hrs photoperiod.

Establishment of Culture

The removed nodal explants (less than 1 cm) were carefully rinsed under running tap water before being surface sterilised in 70% alcohol for 1 minute. Explants were then disinfected with various concentrations of calcium hypochlorite (5, 10, and 20%) at various times during steeping (5, 10, 15 and 20min). Finally, they were cleaned four or five times in sterile distilled water for five minutes each time. With 15ml of nutritive solution, sterile single nodal explants were implanted into test tubes (200 x 24 mm²). The medium contained Murashige and Skoog (1962) mineral salts supplemented with various concentrations and combinations of growth regulators such

as 6-benzylaminopurine (BAP: 0.5,1.0,1.5, and 2.0 mg.L⁻¹), indole-3-butyric acid (IBA: 0.5,1.0,1.5, and 2.0 mg.L⁻¹), enriched with 30 g.L⁻¹ sucrose and gelled with agar (8 g.L⁻¹); 0.4 100 mg.L⁻¹ inositol and L-1 thiamine hydrochloride The pH level was set to 5.8 0.1. White fluorescent tubes provided a photosynthetic photon flux density (PPFD) of 83.6 E m-2s-1 to the cultures, which were kept at 25-28 °C under a 16-hour photoperiod. When determining the sprouting frequency, the appearance of the shoot meristem was taken into account.

Production of Shoots

Shoot tips (1 to 3 cm) received from *in vitro* differentiated shoots had been transferred to MS medium supplemented with distinctive concentrations of BAP (0.5, 1.0, 1.5 and 2.0 mg.L⁻¹) for induction of multiple shoots. The common variety of shoots triggered per explants in addition to the length of the shoots becomes recorded every four weeks.

Induction of Adventitious Roots *in vitro*

Healthy shoots (3 to 4 cm) had been transferred to MS medium containing specific auxins together with IBA and NAA without or with activated charcoal (2.0gmL⁻¹) for rooting. The effect of those auxins on induction of roots from shoots became tested after 30 days of culture. The shoots in the rooting medium had been subjected to both complete darkness for five days or given a 16hrs of light.

Acclimatization of regenerated plants

The healthful plantlets with well- developed roots have been transferred to pots containing a combination of 1/3 sand, 2/3 peat and affirmed in the culture room (25-28 °C at 83.6 µE m-2s-1 PPFD) for 15 or 20 days. The moisture became maintained by covering plants life with a glass cover. The acclimatized plants have been planted in the soil and transferred to field. The percentages of survival were recorded every six weeks.

Data analysis

All experiments were repeated at different times and each treatment had three replicate cultures. Observations regarding number of branches, number of roots and length were recorded at weekly intervals. Significance verification has analyzed in the actual use of SPSS. Data were analyzed using analysis of variance (ANOVA) for a completely randomized design (CRD). Duncan's multiple difference tests was used to separate the mean effect.

RESULTS AND DISCUSSIONS

After three weeks of culture, different changes on lateral bud explants of apple observed. The rate of callus induction was observed and significantly varied amongst the different growth regulators. The data revealed in (Table 1), the frequencies of callus induction had been typically influenced by the concentrations of NAA and kinetin included in the callus induction medium. It has also been observed that the injured areas of explants induce calli

faster than unwounded areas of explants. The greatest calli formed have been recorded on medium supplemented with 2 g/l NAA in combination with 2 mg/l cytoinin. For the propagation stage, the ANOVA analysis substantial effects with diverse kind of concentration of cytokinin were analyzed. The assessment of variance revealed various cytokinin concentrations of BAP and Kn examined had a relatively significant ($p < 0.05$) effects on the number of day to shoot emergence, bud formation, shoot number, shoot length, shoot fresh weight, as well as shoot dry weight of

apples *in vitro* culture techniques. The morphogenetic response of explants for both BAP and Kn concentrations have been summarized in (Table 2). In this study, plant growth regulators have different effects on the proliferation of buds depending on their type and concentration for the different varieties of apples. The report of Siddique and Anis, (2005) reported that explants cultured on MS medium containing 1.50 mg/l of BAP produced a maximum of 11.6 shoot buds per explants.

Mean with the same letter (s) in the same column are not significantly different at $p < 0.005$ according to Fisher's Least Significance difference (LSD). Each value represents a mean $\pm$ S.D. of three independent replicates.

However, in the present study, among the tested cytokinins levels of BAP and Kn, best proliferation had been observed in explants cultured on full strength MS media supplemented with 1 mg/l of BAP (2.97 buds) and 0.5 mg/l of Kn (3.03 buds). In general, when the concentration of BAP increased above 1.5 mg/l in the full strength MS medium, the mean bud formation per explant declined as

showed in (Table. 2). Among the treatment of BAP the best numbers of shoots had been recorded at the higher concentrations 2.0gm/L (14.23) and lowest outcomes had been recorded at lower concentration 0.05mg/L (11.30). The result indicates that with increasing BAP concentration, the appearance of sprouts increased. Concentration and recorded results are directly proportional

to each other. This phenomenon would possibly have limitations. The same is true for Kn treatments, excessive results have been discovered at the higher concentrations 2.0mg/L (17.25) and lower results have been discovered in decrease concentrations 0.5mg/L (12.70) as shown in (Table 2). Overall, effects on shoot treatments higher amount of results were observed in Kn treatments than that of the BAP treatments.

Among the treatments of BAP high amounts shoots were observed per explants in lower concentrations 1.0mg/L (20.47). However, the results were recorded with BAP treatments or concentrations had similarities of the lower of that of 0.5mg/L. The results were presented with BAP concentrations as in the (table 1) above. However, at lower concentrations of Kn high amount of explants were recorded 0.5mg/L (17.04) and at high concentrations lower results were observed 2.0mg/L (14.07). This indicates that the concentration of Kn and the explants observed in these treatments were inversely proportional to each other. The lengths of roots consistent with explants have been high in decrease concentration 0.5mg/L (4.17cm) of BAP and much less in high concentrations 2.0mg/L (3.2cm) of BAP. It is the same with Kn treatments i.e. high value were observed with lower concentrations 0.5mg/L (4.24cm) and lower values were observed with high concentrations 2.0mg/L (3.39cm) of Kn. The present studies revealed with the study with Siddique and Anis, (2005) on the medicinal plants *in vitro* propagation. Shoots fresh weight per explants were highly observed on 0.5mg/L (1.31%) of BAP and 3.20% were observed in lower concentration of BAP. As concentration increases the percentage of shoots fresh weight were increases and vice versa as it indicated in table one above. This results proved that shoots fresh weight per explants and concentrations of BAP treatments of plants were directly proportional each other. The is true of Kn treatments plants. Overall, shoots fresh weight per explants per treatments of BAP treated plants more preferable than that of the Kn treatments. As indicating in Table 2, indicated that the two combinations of BAP and Kn exhibited statistically significance variations on shoot growth parameters (number of shoots, shoot length and shoot fresh and dry weight) among treatments due to hormonal as well as PGRs with varietal interactions. Anilkumar and Nair, (2004) has been reported the effectiveness of combination of 31 mg/l of BAP and 4.6 mg/l Kn for multiple shoot induction from shoot tip explants in *Ipomoea. batatas* L.CV. However, in the present study among the combinations of BAP and Kn, 0.5 mg/L of BAP combined with 2 mg/L of Kn produced maximum mean wide variety of shoots (19.33). The same is true, when 2mg/L of BAP combined with 0.5mg/L of Kn produced maximum mean number of shoots (17.63). The possible justification for the concentration of cytokinin increased beyond the optimal need of the plant, they inhibit the release of endogenous cytokinins and assimilation of the given nutrients by inhibiting the activities of enzymes.

The analysis of variance revealed that the examined auxin concentrations were highly significant ($p < 0.05$) effect on rooting response, main root number, root length,

root fresh weight and root dry weight on *in vitro* resulting shoots of apple plantlets have been presented (Table 3). The data presented in (Table 3) showed that whole basal MS medium was supplemented with unique concentrations of roots induced by IBA and NAA over several weeks of cultivation. The apple combined with the treatment interaction and the main effects of treatment on root response were incredibly large, while genotypes no longer had any effect on root length. Higher roots were observed in apple trees (10.35 cm) at 0.25 mg / L of IBA. The lowest roots were observed (4.81 cm) at 1.0 mg / L IBA. Kayim and Koc (1992) also found a culture *in vitro* regeneration with an interaction with the growing medium on the emergence of apple seed roots. Van et al. (1992) also explored the interaction between apple genotype and sub-cultivation media under *in vitro* conditions for root induction.

The nowadays study show the significant difference were observed in the reaction of plant roots grown on MS media with different concentrations of IBA. These results indicate that the most beneficial environment for root elongation and root development for parent apple lines is the MS environment with low concentration of growth regulators. Zhang et al. (2005) further identified a comparable Golden Pothos response to root response and development *in vitro*. In this study, we identified a unique effect of media genotype on root response. As experience shows, reducing the concentration of IBA has a better reaction of the roots of the seedlings *in vitro* culture. These results are supported by the results of Mumtaz et al., (1989), which indicated that when exposed to high concentrations of growth regulators during proliferation, they do not accumulate storage proteins and are associated with a low frequency of growth regulators. Root response and elongation phase became highly sensitive to auxin concentration and were inhibited by higher concentrations. However, Ahmed et al., (2003) showed that increasing IBA concentration levels to increase the root length of plants for *in vitro* regeneration, but at higher concentrations (4.0 mg / L) they became habitable. The number of main roots formed for sprout explants was significantly influenced by the different species and auxin concentrations used in this study as presented in (Table 3). The greatest numbers of principal roots per explants (9.28) have been reported for grafts of shoots grown on MS medium supplemented with IBA treatments at a concentration of 1.0 mg / L. The minimum number of roots per explant was shown in a medium without hormones as it described (Table 3). As a general observation, the addition of IBA to the media at any of the concentrations tested significantly increased the amount of root regeneration from explants compared to NAA. These results are consistent with those of Khalafalla et al., (2007) reported on the Pear Cactus *Opuntia*.

All of the auxin types and concentrations evaluated in this study (Table 3) permitted the root to develop to a length of 0.0 to 10.96 cm, with a very significant difference ($P < 0.05$) between these values. After two weeks of culture, IBA at 0.25 and 0.5 mg/l generated the longest mean root length (10.35 and 11.10cm) per explant of the two auxins

examined (Table 3). The root length of the above concentrations showed no statistical difference between treatments. In this case, root length is often reported to rise in tandem with an increase in NAA concentration from 0.25 to 1.0 mg/l. At 0.25 mg/L NAA auxin, the highest root length obtained was 10.35 cm (Table 2). In addition to the cultivars that ensured the interaction of the growth medium with the root length of potato seedlings during regeneration, as reported by Kayim and Koc (1992), additional cultivars were observed that ensured the interaction of the growth medium with the root length of potato seedlings during regeneration. Significant changes in root length of plants grown in MS medium with varying concentrations of IBA were also detected in this study. These data demonstrated that MS media coupled with plant growth regulators is the best medium for root elongation and root development of apple parental lines. Chang et al. (2005) discovered similar responses to root elongation and development in Golden Pothos in vitro. The specific

influence of the observed genotype of the nutritional media on root elongation from this perspective. The various IBA concentrations utilised in this study were higher than the ideal concentration for seedling root elongation in vitro. Mumtaz et al. (1989) found that the root elongation phase is very responsive to auxin concentration and is reduced by greater amounts. Yet, Ahmad et al. (2003) discovered that when IBA concentration increases, the length of the root of peach plants grows longer during in vitro regeneration; however, at a greater concentration (3.0 mg / l), it becomes crowded. The maximum mean root fresh weight (2.30g) and root dry weight (1.35g) according to explants had been received on medium containing 0.25 mg/l IBA (Table 3). The maximum root fresh weight and root dry weight value according to explant received from the medium supplemented with NAA (0.25 mg/l) have been 2.30 g and 1.84 g, respectively which can be smaller in comparison with that received on IBA.

Table 3. Effects of concentration of Auxins (IBA and NAA) on morphogenesis response of Root induction o MS medium.

Shoots obtained *in vitro* are very sensitive and susceptible to unexpected environmental changes that can damage young plants unless gradually adapt to a completely new. Thus acclimatization is crucial to allow the rooted plantlets to adapt the natural environment in *ex vitro* conditions. In the acclimatization stage of this experiment, a total of 46 well rooted shootlets for each treatments of plant growth regulators were transferred to pots containing either moist red soil alone, sand alone, compost alone or a mixture of the three culture substrates at ratio of 1:2:1 and acclimatized for one week by irrigating water and aeration daily to maintain the humidity of the plantlets. The acclimatization phase of this experiment found out that the impact of PGR and substrates confirmed big variations at the survival of the *in vitro* regeneration plantlets among varieties as well as amongst treatments (Table.4). Among the examined 4 acclimatized culture substrates, the combination of moist red soil, sand soil, and compost in the ratio of 1:2:1 had confirmed especially big variations at the survival of the *in vitro* regeneration apple plantlets. At this mixture culture substrates, it showed significantly maximum (80.81%) of plantlet survival for observed. There was also the minimum result (53.21%) observed in the treatments with moist red soil alone in the culture substrates of as revealed in the (Table 4). The better survival and acclimatization for longer shoots is in accordance with the recommendations of Peddaboina *et al.*, (2006). Moreover, the essentialities of suitable root devilmint *in vitro* for successful establishment of apple plantlets in the course of acclimatization were consents with Sanatombi and Sharma (2007). Although the document of Venkataiah, (2005) confirmed that plantlets acquired from cytokinins containing media have been effectively established in the soil beneathneath greenhouse situations with a survival frequency of 51.25-80.81%. In cabbage cultivars, plants grown in hormone-free MS media were better acclimatized than those grown in hormone enriched media as described by Stretenovic *et al.* (2002).

Conventional propagation techniques of apple via stem cutting require large amount of materials and space for propagation and a prolonged duration to produce plants. Its regeneration is likewise limited through short period of seed remain viable. These limitations prevent an efficient and rapid production of apple to meet the current market demand for apple. Thus, *in vitro* propagation is normally endorsed to assist the conventional method. The plant tissue culture strategies provide a novel manner for the asexual multiplication of Conventional propagation strategies of apple via stem cutting require large quantity of materials and space for propagation and a prolonged length to produce plants. Its regeneration is also constrained by short duration of seed remain viable. These limitations prevent an efficient and rapid production of apple to meet the current market demand for apple. Thus, *in vitro* propagation is recommended to assist the conventional method. The plant tissue culture methods provide a novel way for the asexual multiplication of apple fruit plants. The *in vitro* regeneration of plants from cell, tissue and organ cultures is a fundamental process for the application of

biotechnology for the propagation, reproduction and genetic development of apple varieties. However, application of cell and molecular biology techniques to apple cultivars genetic improvement is limited because of the difficulties in efficient apple regeneration protocols. Therefore, to overcome those issues and to fulfil the demand for massive scale cultivation in a quick period via mass multiplication, an experiment turned into carried out with the goal mass cultivation the *in vitro* propagation of apple fruit from the explants. The experiment turned into done on the plant Tissue Culture Laboratory and protocol involves four subsequent experiments, viz. *in vitro* callus induction shoot multiplication, root induction and acclimatization of the regenerated plantlets below *ex vitro* condition.

For percentage of callus formation experiment, MS basal medium was supplemented with all concentration levels of NAA combined with 2 mg/l of kn produce more callus compare to control. However, the best callus formation was observed when MS medium was supplemented with 2mg/l NAA in mixture with 2mg/l kinetin. For shoot multiplication experiment, calli had been sub-cultured on MS medium contained 30 gm/l sucrose, 7 gm/l agar, and vitamins supplemented with cytokinins, i.e., 0.5, 1, 1.5, 2 mg/l of BAP or 0.5, 1, 1.5, 2 mg/l of Kn. Moreover, the treatment included the highest and lowest concentrations of the two cythokinins combined alternately. The analysis of the result indicated that there has been a significant distinction among the treatments in addition to among type's interims of shoot growth parameters. Both cytokinins positively enhanced shoot formation of each apple varieties at 0.5 and 1 mg/l concentrations. For the root induction experiment, complete strength MS media fortified with auxins, i.e., 0.25, 0.5 0.75, 1 mg/l of IBA or 0.25, 0.5 0.75, 1 mg/l of NAA had been used. The PGRs had been significant higher rooting effect at 0.25 and 0.5 mg/l than at 0.75 mg/l and 1 mg/l. In the acclimatization experiment, the effect of PGRs into pots containing both moist red soil alone, sand soil alone, compost alone or a combination of the three culture substrates at ratio of 1:2:1 and acclimatized for one week through irrigating water and aeration daily. Among the examined four acclimatized culture substrates, the combination of wet red soil, sand soil, and compost in the ratio of 1:2:1 had confirmed highly sizable distinction for survival (80.81%) *in vitro* regeneration apple plantlets.

CONCLUSIONS

This study provided most suitable protocol for micro-propagation of apple fruit via lateral bud culturing on MS basal medium supplemented with suitable concentrations of various PGRs in sole or combination. This protocol can for that reason be applied to micro-propagate the apple fruit to boost its production. However, more refinement of the protocol is subject to in addition analysis. Based on this study, the following major recommendations are forwarded. Other plant growth regulators such as 2, 4D and 2ip for shoot regeneration and callus induction should be tested. Different strengths of MS media ought to

additionally be examined for callus induction and shoot multiplication. Agronomic overall performance of apple fruit derived from tissue culture regenerated plantlets ought to be tested. Same test ought to additionally be assessed the use of different varieties of apple.

ACKNOWLEDGEMENTS

This paper is a component of Haramaya University research grant coded HURG-2014-01-01-02. Therefore, Haramaya University, office of vice president for research affairs deserves gratitude for this scientific research grant.
